Operando Molecular Science in Liquid–Solid Interfaces of Finite Thickness

We are proud of our international-compatible studies of liquid–solid interfaces, e.g. photocatalysts for artificial photosynthesis and lubricants for smooth tribology. Characterization with frequency-modulation AFM, time-resolved ATR-IR spectroscopy, soft X-ray absorption, and microelectrode-based amperometry are being developed. We are pleased to collaborate with researchers in academic and industrial organizations to reveal science behind material conversion and energy dissipation at liquid–solid interfaces.

A new era of molecular science should be revealed in liquid–solid interfaces of finite thickness (Figure 1). The molecular interface is the place of reaction where molecules of interest collide with or interact with other molecules. We need to observe individual molecules there. On the other hand, the molecular interface is connected to liquid and solid. Materials and energy come from/to the two condensed phases, since functional interfaces are always open to the environment. In addition, operando characterization is definitely required for investigating the interface in its working state.

1. Microelectrode-Based Transient Amperometry of $O_2$ Adsorption and Desorption on a SrTiO$_3$ Photocatalyst Excited under Water

Oxygen evolution at water–solid interfaces is a key reaction for sustainable energy production. Although some intermediate states have been detected in transient absorption spectroscopy, the $O_2$ evolution kinetics after the multi-step, four-electron oxidation of water remain unknown. In this study, transient amperometry with a microelectrode was applied to operando $O_2$ detection over Al-doped SrTiO$_3$ particles doubly loaded with RhCrO$_3$ and Co$_3$O$_4$ cocatalysts, an efficient photocatalyst for the overall water-splitting reaction. A platinum electrode (radius: 10 µm) was moved close to the particles in an electrolyte solution. Molecular oxygen was released on the particles, diffused across the electrode–particle gap, and converted to a current on the electrode (Figure 2).

Electrochemical $O_2$ detection at intervals of 0.1 s, which was thereby achieved, unexpectedly indicated instantaneous $O_2$ adsorption and desorption in addition to steady, photocatalytic $O_2$ evolution on the photocatalyst modified under intense light irradiation. We hypothesized that electrons excited in the conduction band were transferred to $O_2$ in water through Ti cations neighboring an oxygen anion vacancy on the modified Al-doped SrTiO$_3$. The negatively charged $O_2$ was then bound to the Ti cations. It was neutralized and released when shaded through electron back-transfer to the conduction band. The hypothesized mechanism for $O_2$ adsorption and desorption was compared with the photoinduced $O_2$ desorption known to occur on anion vacancies of TiO$_2$(110). The microelectrode-based transient amperometry demonstrated here will be applied to many other phenomena at liquid–solid interfaces.

2. Long-Life Electrons in Metal-Doped Alkali-Metal Tantalate Photocatalysts Excited under Water

Conversion of materials for artificial photosynthesis is completed in milliseconds or seconds by assembling atoms over semiconductor photocatalysts. Bandgap-excited electrons and holes reactive on this time scale are key for efficient atom assembly to yield the desired products. In this study, attenuated total reflection of infrared (IR) light was applied to characterize the electronic absorption of long-life charge carriers excited under water. This was a difficult task since water absorbs IR light for probing, while excitation light is absorbed by photocatalyst particles. An attenuated total reflection (ATR) assembly with a diamond prism is key for guiding the excitation light to the volume probed by IR light (Figure 3).

Under excitation, NaTaO$_3$ and KTaO$_3$ photocatalyst particles doped with Sr or La cations absorbed IR light. A broad absorption band appeared with a maximum at 1400 cm$^{-1}$, which was enhanced by the addition of hole scavengers (e.g., methanol and Na$_2$SO$_4$) and disappeared in the presence of electron scavengers (e.g., FeCl$_3$, NaIO$_3$, and H$_2$O$_2$). This absorption corresponded to the electronic transition of bandgap-excited electrons accommodated in mid-gap states. In anaerobic $n$-decane, the electron absorption was enhanced by the excitation light power, $P$, with absorbance being proportional to $P^{1/2}$. The observed 1/2-order power law suggested de-excitation via recombination of electrons and holes. When the excitation light was stopped, the absorbance decreased as a function of time with a second-order rate law, as expected in the case of recombinative de-excitation. In addition, the 1/2-order power law and second-order decay rate law were observed in anaerobic water, with an accelerated decay rate, which was possibly due to a water-related electron-consuming reaction. This study demonstrated that long-life electrons contribute to surface redox reactions over semiconductor photocatalysts for artificial photosynthesis.
